

Toward an Understanding of Real Estate Homebuyer Internet Search Behavior: An Application of Ocular Tracking Technology

Authors Michael J. Seiler, Poornima Madhavan, and Molly Liechty

Abstract This paper examines the eye movements of homebuyers searching for homes for sale on the Internet. Total dwell time (how long a person looks at the photo), fixation duration (time spent at each focal point), and saccade amplitude (average distance between focal points) significantly explain someone's opinion of the home and its value. The sections that are viewed first are the photo of the home, the quantitative description section, distantly followed by the real estate agent remarks section. Finally, charm pricing, the marketing technique where agents list properties at slightly less than round numbers, works in opposition to its intended effect. Given that homebuyers dwell significantly longer on the first home they view, and since charm pricing typically causes a property to appear towards the end of a search when sorted by price from low to high, we question the wisdom of using a charm pricing marketing strategy.

While it is widely recognized that homebuyers rely more and more on the Internet to pre-search for homes,¹ very little research has examined *how* people search for them on the Internet. With the tremendous wealth of information about listed homes online, potential homebuyers must weigh the marginal search cost (time) of looking through thousands of additional properties against the marginal benefit of possibly finding the home that may be slightly better for them.² If the number of available homes on the Internet was small, people would spend more time looking at each property. But with so many homes available, it is generally accepted that people spend very little time on a particular property. As such, it is important to understand, through the use of quantifiable data, how homebuyers seeking a new home search the net.

Researchers often refer to the difference between “stated preference” and “revealed preference.” A stated preference is what people *say* they prefer or *say* they would do in a certain situation, whereas a revealed preference is what they

actually do. Even a person who is completely honest might experience a divergence between a stated and a revealed preference as many actions occur on a sub-conscious level. Therefore, in order to accurately assess homebuyer preferences, it is important to focus on physiological measures that go beyond simple verbalizations from the user. The purpose of this study is to quantify previously unknown data and thereby advance the field of residential real estate brokerage. Specifically, ocular tracking technology is used to record the exact scanning pattern employed by the homebuyer when searching the web for homes for sale, the number of locations on the screen where they fixate, and the time spent on each fixation point, which serve as indicators of homebuyer revealed preferences during the home search process.

Most behavioral experiments use a convenience sample of student participants. This study makes an additional contribution in that both students and actual homebuyers currently searching for a primary residence are examined. A comparison of the sub-sample results provides a direct test of the extent to which substitution should be deemed acceptable in behavioral experiments between convenient and actual subject samples. The results vary in several key areas and when possible, subject sample data should be directly collected.

In examining the sequence of each component of the webpage that is viewed, the photo is overwhelmingly viewed first, followed by the property description section, and lastly, the real estate agent open remarks section. Actual homebuyers pay somewhat more attention to these later two sections when viewing the opening page of the home tour than do students. This may be because students are not actually in the market to buy a home.

Finally, this paper contributes to the literature on charm pricing, the marketing technique where agents do not round off the listing price to the nearest \$1,000 or even \$10,000. Instead, prices are listed at slightly lower than round numbers (e.g., \$299,900 vs. \$300,000). Rationally, this \$100 should have almost no impact on homebuyer opinion of value, yet Allen and Dare (2004) have shown it to be an effective pricing strategy. In opposition to Allen and Dare (2004), the results of the current study support the findings of Palmon, Smith, and Sopranzetti (2004) in that charm pricing is found to work against the seller. When coupled with the finding that homebuyers spend the greatest amount of time looking at the first home that results from their search, the results do not support the use of charm pricing strategies.³

Literature Review

Eye movements are arguably the most frequent of all human movements. Large scanning movements called saccades typically occur 3–4 times every second; the search pattern followed by the eyes as they saccade from one point to another is called the scanpath; and, the amount of time spent at each point is the fixation time. Eye tracking as a methodology is based on Just and Carpenter's (1976) "eye-

mind” hypothesis: the location of a person’s gaze directly corresponds to the most immediate thought in a person’s mind. In usability testing and advertising, eye tracking is useful because it can be used to measure behavior that would be difficult to obtain through other more overt measures (Karn, Ellis, and Juliano, 2000). Due to their close relation to attentional mechanisms, saccades can provide insight into cognitive processes such as picture comprehension, memory, mental imagery, and decision making. Thus, eye movement research has historically been of great interest in the fields of neuroscience and psychiatry, as well as ergonomics, advertising, and industrial design.

Eye tracking research that is most relevant to this study has been found in the following areas: (1) reading print and online material, and (2) searching and scanning webpages. Eye tracking studies of reading behaviors have yielded interesting and useful findings about how people visually interact with documents. Much of the usability-related research in this area centers on how variations in textual and graphical presentation affect behavior (Brysbaert and Vitu, 1998). When readers encounter cognitively complex material, the rate at which they read slows considerably as shown by increases in eye fixation times and number of regressions (backtracking) and decreases in saccade lengths (Liversedge, Paterson, and Pickering, 1998). Furthermore, variations in type sizes affect the normal range of eye fixation durations, saccade movements, and regressions (Tinker, 1963). In studies of online reading, researchers have found that excessive use of color⁴ decreased reading speeds by as much as 30% to 40% (Krull and Rubens, 1987), although more recent studies have seen an increase in retrieval times due to participants being more familiar with computers (Krull, Sundararajan, Sharp, and Potts, 2004). As with reading, eye tracking research has provided insight into how people scan and search for information online. This has been done in using two methods: (1) in targeted-search studies, people are asked to identify specific information or perform a predefined task, and (2) in free-scan studies, people are asked to view a screen or series of screens without any predefined goal.

In general, it has been found that people prefer text over graphics as entry points into websites (Boaz, Cuneo, Kreps, and Watson, 2002). Also, eye movements roughly followed the “Z” pattern of design. People’s eyes first travel to the upper left corner (typically where the website identifying logo is placed), across the page to the right corner, and then continue scanning the page in small “z” patterns progressing down the page (Goldberg, Stimson, Lewenstein, Scott, and Wichansky, 2002). Interestingly, scanning did not end at the bottom right corner, but instead continued up the right column of the page.

In addition, small type encouraged focused reading behavior while large type promoted light scanning. When scanning, people are looking for words or phrases that catch their attention. Images of at least 210 X 230 pixels received more eye traffic than smaller images, and people frequently clicked on the 210 X 230 pixel images. Interestingly, scanpath analysis revealed that users do not necessarily follow the same scanpath for every type of website. Instead, there appear to be universal scanpaths that people develop based on the function, genre, and design of a website (Josephson and Holmes, 2002).

Data and Design

To understand how homebuyers search for homes on the Internet, it is necessary to perform tests on actual homebuyers. Twenty⁵ currently searching or recent (within the last three months) homebuyers from the local area who are in the market for a home in the price range of \$285,000–\$350,000 were invited to participate in this study.⁶ Twenty-five university students serve as the control group.⁷ These 45 individuals were shown 10 homes, each containing 6 photographs. The result is a cross-sectional dataset containing 450 (45 people \times 10 homes) completed home tours and a total analysis of 2,700 (450 \times 6) photos.⁸ To our knowledge, this constitutes the largest sample collected in a study using an ocular tracking methodology.

Participants were seated in front of a computer equipped with a 17-inch CRT monitor (optimal for ocular tracking due to its refresh rate). Below the monitor was a desk-mounted, unobtrusive ocular tracking hardware/software (Eyelink 1000) device.⁹ When using the device, the participant positions his chin on a padded shelf with his forehead resting against a padded frame.¹⁰ Once calibrated for that particular participant, a PC-based remote camera then records all eye movements. The task involves participants taking 10 different home tours on what effectively is the Internet.¹¹ The website intentionally reflects the appearance of those currently in existence. Specifically, the opening page has three primary components. The first is an enlarged curb appeal photograph that listing agents hope will catch the eye of the viewer. Underneath this large photo are five thumbnail pictures of the remaining rooms in the home. The second section is located in the upper right-hand portion of the page and includes property statistics such as square footage, number of bedroom/bathrooms, and so forth. The third and final section of the opening page shares real estate agent remarks, which is an opportunity for the agent to help sell the property. Exhibit 1 shows the layout of the website.

Once the opening page is viewed, the participant can search the six component pictures of the home (curb appeal, main living area, kitchen, master bedroom, master bathroom, and view/backyard). The participant is allowed an unlimited time to view each picture and may move forward in the search at any time simply by clicking a button. After the six photos of the first home are shown, a series of short questions is asked, which allow for the measurement of the user's ratings. The data were analyzed via content analysis, a technique described later in this paper. After answering the questions, the second home is shown, followed by a few questions about that home, and so forth. After five homes have been viewed, the participant is allowed to take a short break and then continue to complete the second half of the tours. At the end of the visual portion of the experiment, the participant is asked to share basic demographic data (such as gender, age, marital status, ethnicity, income, etc.).

For validity of design, these general survey questions were alternated between the beginning and the end of the visual portion of the experiment (to prevent such

Exhibit 1 | Sample View of the Website Design with an Ocular Tracking Variable Analysis Superimposed

This exhibit shows the first page the participant sees. It includes an indication of the interest areas, as well as various superimposed ocular tracking measures.

biases as cognitive anchoring). Other design mechanisms implemented to prevent respondent bias include randomizing the order of the 10 homes that are shown (to prevent order effects), as well as randomizing the order of the five pictures beneath each home. Note that the curb appeal design mechanisms were put in place to minimize the potential for introducing bias, while at the same time keeping the search process as realistic as possible.¹² Because of the expensive equipment used and the need to avoid outside distractions, it was necessary to bring actual homebuyers to the university study site. For this reason, they were compensated with a \$50 gas card redeemable at a nearby gas station.¹³ Student participants were from psychology classes and were given experiment participation credit, a practice very common in the field.

Methodology

Since no known study of this type has ever been conducted within a real estate setting, the analysis begins with a series of univariate tests and design verification procedures. Afterwards, a direct test of whether or not ocular tracking variables can be used to predict the willingness of a homebuyer to pay for a home is considered based on several variations of the following equation:

$$\text{Home Value} = f\{\text{Home Characteristics, Qualitative Variables, Ocular Tracking Variables, Demographic Characteristics, Miscellaneous, error}\}. \quad (1)$$

Where the specific variables are defined as follows:

Dependent Variables

- % List Price* = The participant's opinion of fair market value minus list price, divided by list price;
- Market Value Opinion* = Participant's opinion of the fair market value of the home;
- Worth More Dummy* = A dummy variable equal to 1 if the participant estimates the fair market value of the home to be greater than the listing price; 0 otherwise;
- Worth Less Dummy* = A dummy variable equal to 1 if the participant estimates the fair market value of the home to be less than the listing price; 0 otherwise; and
- Overall Home Rating* = Participant's overall rating of the home on a scale from 1 (not at all favorable) to 9 (extremely favorable).

Home Characteristics

- Actual Rating of the Rooms* = Participant's ex post rating of the specific room (photo) for the curb appeal, kitchen, main living area, master bedroom, master bathroom, and backyard/view on a scale from 1 (worst ever) to 9 (best ever); and
- Importance of the Rooms* = Participant's ex ante importance rating of the specific room (photo) for the curb appeal, kitchen, main living area, master bedroom, master bathroom, and backyard/view on a scale from 1 (not at all important) to 9 (very important).

Qualitative Variables

- Total # of Words* = Total number of words the participant used to describe the home after the tour;
- # Positive Words* = Number of positive words the participant used to describe the home after the tour;
- % Positive Words* = Percentage of positive words (to total words) the participant used to describe the home after the tour;
- # Negative Words* = Number of negative words the participant used to describe the home after the tour; and

% Negative Words = Percentage of negative words (to total words) the participant used to describe the home after the tour.

Ocular Tracking Variables

<i>Total Dwell Time</i>	Total time spent looking at each picture (in milliseconds);
<i>Fixation Duration</i>	Average time spent at each fixation point within each picture (in seconds);
<i># of Fixations per Picture</i>	Number of points on the screen where the participant's eye stopped (i.e., fixated);
<i>Saccade Count</i>	The number of times the participant's eye jumped from one fixation point to the other; and
<i>Saccade Amplitude</i>	Average distance between fixation locations (computer screen distance).

Demographic Characteristics

<i>Gender</i>	Male = 0; Female = 1;
<i>Age</i>	Age in years;
<i>Income</i>	Annual income level (0 = \$0–\$20,000; 1 = \$20,001–\$40,000; 2 = \$40,001–\$60,000; 3 = \$60,001–\$80,000; 4 = \$80,001–\$100,000; 5 = \$100,001–\$120,000; 6 = Over \$120,000);
<i>College Degree</i>	1 = College degree; 0 = No college degree;
<i>Homeowner</i>	1 = Has purchased a home before; 0 = Otherwise;
<i>Homes Purchased</i>	Number of homes purchased in lifetime;
<i>Married</i>	1 = Married; 0 = Single; and
<i>White</i>	1 = White; 0 = Non-White.

Miscellaneous

<i>Consumption Motive</i>	1 = Consumption motive only; 0 = Otherwise;
<i>Investment Motive</i>	1 = Investment motive only; 0 = Otherwise;
<i>% of Search on Web</i>	Home search time spent on the web (as a percentage of total home search time);
<i>Familiarity with Market</i>	Familiarity with the real estate market in the local area on a scale from 1 (not at all familiar) to 9 (extremely familiar); and
<i>Charm Pricing Dummy</i>	1 = Charm pricing was used in the list price; 0 = Otherwise.

Dependent Variables

Agarwal (2007) and Seiler, Seiler, Lane, and Harrison (2012) document that people are not proficient at identifying the true value of the home in which they live. If this is the case, then asking them to accurately place a fair market value on a home they have only visited through a virtual tour would seem more

daunting. Still, in economics, finance, and real estate, the concern is with the amount people are willing to pay for a home more so than just how a person rates the overall quality of the home. While a measure of homebuyer willingness to pay is preferred to a simple rating of the home, there are numerous difficulties with collecting this data through a controlled experiment. For this reason, both measures are collected and a series of regressions are performed accordingly. Additionally, we further segment the analysis based on those who believe the home they viewed is worth more (or less) than the listing price offered by the selling agent via a series of logistic regressions.

Home Characteristics. Ex ante homebuyer stated preferences are collected in terms of which rooms inside the home they believe to be the most important in the final assessment of whether or not they will like the home. These importance measures are then correlated with the ex post ratings of how much the homebuyer liked the rooms, as well as the overall home rating. Real estate agents often use the phrase “buyers are liars” to describe the frustration of showing clients exactly what they ask to see only to eventually have them buy a property whose attributes do not even remotely resemble the original “must have” list. While it is not the central focus of the investigation to fully pursue this research question, we do take a cursory glance at the issue.

Qualitative Variables. Buying a home can be a very difficult and time-consuming process. Not only is the purchase likely the largest an individual will ever make, but the selection of a home is one based on both economics and emotion. After completing each tour, participants are asked to share the words that come to mind when thinking about the home they just toured. The list of words may at times seem to represent a stream of unconsciousness. However, using textural data analysis techniques such as those in Li (2008), Dempsey, Harrison, Luchtenberg, and Seiler (2012), it is possible to classify these words as being positive, negative, or neutral. From this process, we are able to create and include in the quantitative analysis a number of variables that were previously considered too qualitative.

Ocular Tracking Variables. One of the key contributions of this study is to quantify variables that have previously been impossible to capture. Through the use of modern technology, we are able to record with incredible precision five key ocular tracking variables. The first is the total dwell time (in milliseconds) that each participant spends looking at each of the 2,700 photos in the sample. Past studies have shown that an increase in total dwell time is an indication of viewer interest. Dwell time is hypothesized to have a positive association with interest in the photo. A second captured measure is the number of fixation points (referred to as fixation count) when viewing each of the photos. Fixation points represent locations where the viewer has slowed down to take a closer look at a photo. Fixation duration is the average time spent at each fixation point (typically in milliseconds). A greater number of fixation points is hypothesized to be an indicator of either greater interest or more effort expended in viewing the image since evidence indicates that intense cognitive processing occurs during a fixation (Rayner, 1998).

Saccade count is the number of times a participant's eye jumped from one fixation point to another. A related measure is saccade amplitude. This variable measures the average distance between fixation locations. Although there are several different interpretations of a saccade in the ocular tracking literature, it is generally accepted that when a saccade occurs, information is being suppressed (Rayner, 1998). Thus, the greater the number and length (amplitude) of saccades, the less time an individual was focusing on or actively interpreting the information in front of them. This could mean that greater saccade counts and longer saccade amplitudes imply: (1) a lower level of interest in the visual scene, or (2) a higher level of familiarity with the task/context and low need to search very thoroughly. Each of the five ocular tracking variables is collected for all 2,700 photos viewed.

Demographic Characteristics. Because people of all demographic profiles search for homes on the Internet, it is not the focus of this study to examine the scanpath differences by demographic characteristics. Still, the data does allow for the inclusion of these as control variables. It is also interesting to see how the results change when moving from actual homebuyers to a convenience sample containing only students. As previously stated, the overwhelming majority of experiments are conducted on student samples due to ease of access. The question is the degree to which students provide a sufficient proxy for a sample of actual homebuyers.

Miscellaneous. Flachaire, Hollard, and Luchini (2003) used a novel approach to measure a variable they termed "conformist versus non-conformist" in a study of a participant's willingness to pay for admission to a park. The process involves respondents answering a simple open-ended question: "When you think of (the park), what words come to mind?" Then, after a series of iterative steps similar to a factor analysis, a dummy variable is formed that allows for a quantification of a previously strictly qualitative concept. This approach is used to see whether or not the manner in which a homebuyer views a home (as a consumption good vs. an investment) influences a willingness to pay for the property.

The percentage of search time on the web is also collected with the notion that more experienced searchers might view webpages differently than those who are new to the process. For example, experienced searchers likely do not need nearly as much time to view an Internet real estate listing because they have seen so many already and presumably know what they are looking for. The next independent variable is familiarity with the local residential real estate market. Increased familiarity should also influence the search process in a manner similar to experience on the web.

Charm pricing is an employed marketing technique whereby the list price of a residence is set just below a round number (e.g., \$299,900 vs. \$300,000). While several studies, such as Miller and Sklarz (1987), Kang and Gardner (1989), Asabere, Huffman, and Mehdiian, (1993), Knight, Sirmans, and Turnbull (1994), and Benjamin and Chinloy (2000), have examined the relationship between list price and sales price in a macro sense, only two studies have directly examined charm pricing in residential real estate. Allen and Dare (2004) examined

transactions in south Florida and found charm pricing in listed properties to lead to higher transaction prices. In direct contrast to their study, Palmon, Smith, and Sopranzetti (2004) found the opposite result when examining price behavior in Texas. Because the literature remains sparse in the charm pricing area, this variable is included as a secondary contribution of this study.

Results

Panel A of Exhibit 2 displays the total dwell times by the order in which the home was shown. Recall that the home order was semi-randomized to prevent order effects bias in the results. What is evident from the exhibit is that the first home shown to participants took longer to view than those that follow. A learning curve such as this is expected with any new experience. So while someone in the market for a new home has likely searched for homes on the Internet before, this is the first time they have seen this particular website. The curve levels off almost immediately as the dwell time to view homes in positions 2 through 10 are rarely significantly different from each other. Since most search engines for residential real estate show results sorting prices from low to high, sellers might want to list their properties at the very bottom of the pricing interval. This would cause their home be shown first, which is associated with a longer dwell time by the potential buyer.¹⁴

Panel B of Exhibit 2 considers the order effects of rooms within the homes. Recall that the curb appeal photo was always shown first to the participant as this is the common industry practice. The photos shown beneath it randomly shuffle through the remaining rooms, which is also consistent with both cyberspace and physical tours of a home. ANOVA and post hoc tests reveal very few significant differences in dwell times for any of the rooms, suggesting that participants maintained a fairly consistent speed while scrolling through the website.

Summary statistics for the dependent variables in Equation (1) are listed in Panel A of Exhibit 3. As expected, both homebuyers and students estimate the true market value of the home to be less than the list price. This is consistent with both observational intuition and cognitive anchoring hypotheses. Both groups estimate prices to be over-stated by roughly 5%–6%. Interestingly, homebuyers report a higher market price for the homes, but a lower overall rating when compared to students. This conflicting result is often argued to exist in studies that are published in psychology versus real estate/finance journals and was the impetus for collecting both metrics in this investigation. There are no statistically significant differences in Panel A, however.

Panel B of Exhibit 3 displays the ex post or actual ratings for each photo of the home followed by the ex ante stated level of importance when evaluating a residence. While four of the six importance ratings are statistically significantly different between the two groups of sample participants, only one (a different room) was significant in terms of ex post evaluation. After the home was toured,

participants were asked what words come to mind when thinking of the home just toured. Using content analysis (Berelson, 1952), these terms were coded based on three concepts: positivity, negativity, and neutrality. Using responses to the survey questions given to each participant in the beginning (or ending, for the other half of the sample) of the study, each word was then further coded based on a relational analysis, meaning that the underlining concept of each word coded was cross-referenced with the participant's verbal description of each property immediately after it was viewed. Coding participant data in this manner is a typical method for trying to understand the mental models participants construct (Carley and Palmquist, 1992; Flachaire, Hollard, and Luchini, 2003). While homebuyers use significantly more words to describe the home, both groups are remarkably similar in both their number and percentage of positive and negative words.

Significant differences between homebuyers and students only begin to emerge when considering the ocular tracking variables presented in Panel D of Exhibit 3. Specifically, homebuyers take significantly less time to view each room when compared to students. This result is fully anticipated given that they have already been searching for homes and therefore better know what they are looking for when perusing a website. A similar pattern of significant differences between the homebuyers and students is seen in the number of fixations per picture and saccade count. Consistent with expectations, experienced homebuyers fixated less and demonstrated fewer saccades indicating that experience and familiarity with the context compensated for the need to search thoroughly. However, this could also be an indication of low interest in the website display (Rayner, 1998), which poses an additional challenge when designing for the experienced buyer. Without the use of ocular tracking technology, these challenges would never be known.

Understandably, the demographic profiles between homebuyers and students differ considerably. Homebuyers in the sample are significantly older, earn more income, have a higher level of education, have owned more homes in the past, and are more likely to be married. They also have a significantly greater percentage of search time on the web and a greater familiarity with the local residential real estate market. Finally, homebuyers are more likely to consider the investment component of a home when making a purchase. In fact, not one of the 25 students associated strictly investment-related words when buying a home compared to 16% of homebuyers. Similarly, the consumption only motive was mentioned in 80% of student cases as opposed to just 62% of homebuyers. Clearly, a homebuyer is thinking more in terms of both consumption and investment when searching for a home.

In sum, the demographic profile between homebuyers and students is significantly different across almost every measure, and while the groups do not seem to agree on what they are looking for in a home (*ex ante*), the *ex post* results reported thus far are strikingly similar with the exception of three of the five ocular tracking variables.

Exhibit 4 displays the sequence in which participants viewed the three sections of each webpage. Panel A reveals the analysis associated with the curb appeal

Exhibit 4 | Viewing Order for the Curb Appeal and Main Living Areas

Viewing Sequence	Photo	Quantitative Property Description	Agent Remarks
Panel A: Curb Appeal Sequential Analysis			
Viewed First	95.1%	2.4%	2.4%
Viewed Second	2.4%	75.6%	7.3%
Viewed Third	2.4%	7.3%	48.8%
Not Viewed	0.0%	14.6%	41.5%
Panel B: Main Living Area Sequential Analysis			
Viewed First	87.8%	7.3%	4.9%
Viewed Second	12.2%	29.3%	2.4%
Viewed Third	0.0%	2.4%	4.9%
Not Viewed	0.0%	61.0%	87.8%

photo, which is always seen first by the participant. Overwhelmingly (95.1%), participants first look at this picture. After focusing on the photos, participants next turn to the quantitative property description section where the number of bedrooms, bathrooms, square footage, etc. is displayed. Finally, the real estate agent’s open remarks section is viewed. Very little emphasis is placed on this section. In fact, over 40% of all participants (20% of homebuyers; 62% of students) do not even look at the real estate agent remarks when viewing the first page of the home tour. Participants comply by viewing the remainder of the home, but in an actual setting, one has to wonder if the agent remarks would ever get read if the home searcher does not like the initial photo of the home.

Panel B of Exhibit 4 reports the sequence of viewing for a later page in the home tour. Recall that after the curb appeal, the remaining rooms are rotated to appear in any order. As such, we sample the main living area and generate viewing patterns for these rooms. Similar to the curb appeal, participants clearly focus on the photo of the room as opposed to reading the quantitative property description, and finally the agent’s remarks. This is understandable since these latter two areas have been present on every page, whereas the photo is new on each subsequent page.

When parsing the data, homebuyers are much more likely to view all three sections of the webpage whereas students focus much more on the photos. This is understandable as homebuyers are actually in the market to buy these properties, and as such, need to collect as much information as possible to reach an informed decision. Gender did not play a role in determining search sequence.

Panel A of Exhibit 5 correlates dwell time with the ex ante stated preference of what is important to participants. Correlation coefficients are either insignificantly different from zero or significantly negative. The interpretation is that a person does not have to look at a photo for a long time to gather from it the information necessary to reach a conclusion. In fact, the opposite is true. People seem to be more efficient at gathering information when the photo is of greater importance. Panel B relates the ex post evaluations of the overall home rating to the individual rating of each room. While all rooms are significantly positively correlated with the overall rating, no room in particular stands out as being a better indicator of the overall home evaluation. Finally, Panel C correlates the five ocular tracking variables to decide which ones should not be included in the estimation of Equation (1) due to multicollinearity concerns.

Exhibit 6 reports the results from six different variations of estimates to Equation (1).¹⁵ In the first three regressions, the dependent variable is the participant's estimate of the home's value as a percentage of the list price. Recall that price is a measure more palatable to real estate economists. The fourth through sixth regressions have the overall home rating on a scale from 1 to 9 as the dependent variable, which is a measure used more in psychology studies. Unreported correlations indicate that multicollinearity concerns prevent the inclusion of all the demographic variables. Therefore, in the first regression, a dummy variable for participant type was used to capture differences between homebuyers and students. Consistent with the results in Exhibit 3, homebuyers and students are heterogeneous between groups, but extremely homogeneous within each group. As such, only low correlated variables are included in each subsequent regression.

As hypothesized, the percentage of negative words is significantly negative in all three regressions.¹⁶ Total dwell time and fixation duration are significantly positive and driven primarily by the student sample, while the statistically negative coefficient on saccade amplitude is driven primarily by the homebuyer sample. Homebuyers with a higher income perceive prices to be significantly lower than lower income buyers, presumably because they are in the market for higher priced (and therefore, nicer) homes. The same relationship is true for experienced homebuyers. They appear not to be as easily impressed as less seasoned buyers. Consistent with univariate tests, the negative coefficient on the participant type dummy variable indicates that students perceive the value of homes within the sample to be lower than the perception of value by homebuyers. Finally, the significantly negative coefficient on charm pricing is consistent with Palmon, Smith, and Sopranzetti (2004) in that the technique works in the opposite direction as intended.

When comparing the results from the percentage of list price regressions to the results from the overall home rating regressions, the dependent variable does seem to make a difference. The sign changes for three of the variables (total dwell time, consumption motive, and participant type). In two of the cases, the variable becomes insignificant, but in the case of the consumption motive, the sign changes direction and significance. While it is not possible to know which dependent

variable is a better choice on which to base the analysis, it is simply our purpose to identify the fact that the two measures, at times, yield significantly different results. This is a topic we suggest future studies delve into further.

Exhibit 7 reports six separate logistic regression results from two variations of Equation (1). Otherwise similar to the specifications in the prior exhibit, the new dependent variable for the first three columns is a dichotomous variable, set equal to one if the participant believes the home is worth *more* than the list price and zero otherwise. In the last three logistic regressions, the dependent variable is set equal to one if the participant believes the home is worth *less* than the list price. For the full sample logistic regression in the first column, as expected, the percentage of positive words carries a significantly positive coefficient as does total dwell time and fixation duration. These results are clearly driven by the student portion, where the signs and significance levels are consistent. Alternatively, for the homebuyer sub-sample, only the numbers of homes purchased in the past is significant.

In the three logistic regressions attempting to model the causes of participants who believe a home is worth less than its list price, the percentage of negative words used to describe it replaces the percentage of positive words. Consistent with expectations, the coefficient is positive and significant. The signs for fixation duration and saccade amplitude have switched when moving from the worth *more* to worth *less* regressions, as expected. Fixation duration not only switched signs, but also retained its statistical significance. This means that when a person likes the home, they fixate for greater periods of time. Conversely, when they do not like it, they experience shorter fixation periods. In both of the full sample logistic regressions, the variable, participant type, is not significant.

Charm pricing results in Exhibit 7 are consistent with Exhibit 6. In the first three columns, the charm pricing dummy carries a significantly negative signal, indicating that its use resulted in fewer homebuyers evaluating the home as being worth more than the list price. Consistently, in the last three columns, the coefficients on charm pricing are all significantly negative, indicating a symmetrical relationship. The conclusion is that charm pricing worked against its intended purpose, consistent with the findings of Palmon, Smith, and Sopranzetti (2004), but opposite the conclusions Allen and Dare (2004).

Conclusion

This study compared the results of actual homebuyers versus a convenience sample of university student participants. While the demographic differences are stark, the results typically are not. However, significant differences are observed in a number of the ocular tracking variables: total dwell time, number of fixations, and saccade count. We find that homebuyers and much more so students, focus primarily on the photo of the home and secondarily on the quantitative description of the property. Real estate agent remarks are substantially lower on the list of

priorities. Just over 40% of participants did not view these remarks when looking at the first page of the website. This speaks to the revealed importance of real estate agent remarks to people searching for a home. In an examination of home prices, charm pricing has the opposite effect as intended (a negative relationship with price). The literature has been mixed on the success of this marketing technique.

Since this is the first study to use ocular tracking technology in a real estate setting, we focused on fundamental concepts and an exploratory understanding of how people search for homes on the Internet. Future studies should extend the work described here by testing the impact on various website designs. By performing a similar analysis, after altering the layout of the page, real estate agents can begin to learn which designs best grab the homebuyers' attention. Moreover, in future studies, it would be beneficial to simply observe homebuyers in their natural element where they are free to continuously surf the Internet for homes without having to pause periodically and answer questions about what they have just seen. Still the initial steps taken in the current investigation are necessary groundwork before more advanced investigations can be considered.

Endnotes

- ¹ See Bond, Seiler, Seiler, and Blake (2000) and Benjamin, Chinloy, Jud, and Winkler (2005) for the homebuyer market, as well as Hagen and Hansen (2010) for the rental market.
- ² See Gwin (2004).
- ³ The results from home searches typically yield properties listed in a price order from lowest to highest. Since charm pricing results in a greater likelihood of being toward the higher priced home order within the search range, it would seem that charm priced homes would be seen much later by the homebuyer, who might be more prone to fatigue and therefore, skim-reading.
- ⁴ The degree of color is typically quantified by dividing the portion of the page that is in color by the total page size. The definition of "excessive" varies from study to study.
- ⁵ The sample is split between 10 females and 10 males. Also, for married participants, only one member (husband or wife) was allowed to participate to avoid duplication of stated preferences.
- ⁶ This research was supported by three local real estate brokerage firms whose presidents serve on the authors' real estate center's board. These firms kindly directed current clients for inclusion consideration.
- ⁷ The overwhelming majority of these types of studies examine only students because it is far easier to collect student data. We also collect student data simply to examine how results vary between this convenience sample and those from the population of homebuyers in whose behavior we are most interested.
- ⁸ All photographs used were from homes currently on the market in the Hampton Roads, Virginia area. Original photographs were obtained directly from REIN, the company in charge of posting photos for the local MLS.

- ⁹ Participants must not be color-blind and must have normal or corrected-to-normal vision, since this is a primarily visual experiment with colored stimuli presented on a computer screen.
- ¹⁰ Other than these two somewhat parallel bars, nothing stands between the participant and the monitor.
- ¹¹ Technically, the tours take place on a self-contained, originally created program that allows the authors to completely control the process and avoid outside influences like pop-up advertisements and connectivity loss. The result is a seamless, uninterrupted home tour that allows tracking of ocular tracking-related variables of interest.
- ¹² The entire process takes 35–45 minutes to complete.
- ¹³ The institution who supported this research via a large grant did not allow the distribution or handling of cash. The gas card was an acceptable alternative and thought to be nearly as good an incentive as cash.
- ¹⁴ Clearly, this only makes sense if the market value of their home is extremely close to the lower pricing level already.
- ¹⁵ Because each participant views 10 homes, nine ($n - 1$) “home number” dummy variables are included in each regression to control for fixed effects.
- ¹⁶ When the percentage of positive words is included instead, the result is a consistently positive and significant coefficient. As such, either variable (but not both due to their significant negative correlation) can be used in the regressions.
